Testing st-Connectivity

Sourav Chakraborty* Eldar Fischer† Oded Lachish‡ Arie Matsliah§ Ilan Newman¶

Abstract

We continue the study, started in [9], of property testing of graphs in the orientation model. A major question which was left open in [9] is whether the property of st-connectivity can be tested with a constant number of queries. Here we answer this question on the affirmative. To this end we construct a non-trivial reduction of the st-connectivity problem to the problem of testing languages that are decidable by branching programs, which was solved in [11]. The reduction combines combinatorial arguments with a concentration type lemma that is proven for this purpose. Unlike the case for many other property testing results, here the resulting testing algorithm is highly non-trivial itself, and not only its analysis.

1 Introduction

We continue the study, started in [9], of property testing of graphs in the orientation model. This is a model that combines information that has to be queried with information that is known in advance, and so does not readily yield to general techniques such as that of the regularity lemma used in [1] and [3].

Specifically, the information given in advance is an underlying undirected graph $G = (V, E)$ (that may have parallel edges). The input is then constrained to be an orientation of G, and the distances are measured relative to $|E|$ and not to any function of $|V|$. An orientation of G is simply an orientation of its edges. That is, for every edge $e = u, v$ in $E(G)$ an orientation of G specifies which of u and v is the source vertex of e, and which is the target vertex. Thus an orientation defines a directed graph $\vec{G}$ whose undirected skeleton is G. Given the undirected graph G, a property of orientations is just a partial set of all orientations of G.

We study orientation properties in the framework of *property testing*. The meta problem in the area of property testing is the following: Given a combinatorial structure S, distinguish between that case that S satisfies some property $\mathcal{P}$ and the case that S is *ϵ-far* from satisfying $\mathcal{P}$. Roughly speaking, a combinatorial structure is said to be ϵ-far from satisfying some property $\mathcal{P}$ if an ϵ-fraction of its representation should be modified in order to make S satisfy $\mathcal{P}$. The main goal in property testing is to design randomized algorithms, which look at a very small portion of the input, and use this information to distinguish with high probability between the above two cases. Such algorithms are called *property testers* or simply *testers* for the property $\mathcal{P}$. Preferably, a tester should look at a portion of the input whose size is a function of ϵ only and is independent of the input size. A property that admits such a tester is called *testable*.

Blum, Luby and Rubinfeld [4] were the first to formulate a question of this type, and the general notion of property testing was first formulated by Rubinfeld and Sudan [14], who were interested in studying various algebraic properties such as the linearity of functions. The definitions and the first study of property testing as a framework were introduced in the seminal paper of Goldreich, Goldwasser and Ron [6]. Since then, an extensive amount of work has been done on various aspects of property testing as well as study of particular properties. For comprehensive surveys see [13, 5].

Here the relevant combinatorial structure is an orientation $\vec{G}$ of the underlying graph G, and the distance between two orientations $\vec{G}_1,\ \vec{G}_2$ is the number of edges that are oriented differently in $\vec{G}_1$ and $\vec{G}_2$. Thus an orientation $\vec{G}$ is *ϵ-far* from a given property P if at least $\epsilon|E(G)|$ edges have to be redirected in $\vec{G}$ to make it satisfy P. Ideally the number of queries that the tester makes depends only on ϵ and on nothing else (neither $|E|$ nor the specific undirected graph G itself).

A major question that has remained open in [9] is whether connectivity properties admit such a test. For a fixed $s, t \in V(G)$, an orientation $\vec{G}$ is st-connected if there is a directed path from s to t in it. Connectivity and in particular st-connectivity is a very basic problem in graph theory which has been extensively studied in various models of computation.

Our main result is that the property of being st-connected is testable by a one-sided error algorithm with a number of queries depending only on ϵ. That is, we construct a randomized algorithm that for any underlying graph G, on input of an unknown orientation the algorithm queries only $O(1)$ edges for their orientation and based on this decides with success probability $\frac{2}{3}$ (this of course could be amplified to any number smaller than 1) between the case that the orientation is st-connected and the case that it is ϵ-far from being st-connected. Our algorithm additionally has one-sided error, meaning that st-connected orientations are accepted with probability 1. Note that the algorithm knows the underlying graph G in advance and G is neither alterable nor part of the input to be queried. The dependence of the number of queries in our test on ϵ is triply exponential, but it is independent of the size of the graph.

To put our result in context with previous works in the area of property testing, we note that graph

properties were extensively studied since the early beginning in the defining paper of Goldreich, Goldwasser and Ron [6]. The model that was mainly studied is the *dense graphs* model in which an input is a graph represented as a subgraph of the complete graph. As such, for n-vertex graphs, the input representation size is $\binom{n}{2}$ which is the number of all possible unordered pairs. Thus, any property that has $o(n^2)$ witness size, and in particular the property of undirected st-connectivity, is trivially testable as every input is close to the property. Similarly, properties of directed graphs were studied in the same context mostly by [1, 3]. Inputs in this model are subgraphs of the complete directed graph (with or without anti parallel edges). In this case, directed st-connectivity is again trivial.

Other models in which graph properties were studied are the *bounded-degree* graph model of [7] in which a sparse representation of sparse graphs is considered (instead of the adjacency matrix as in the dense model), and the *general density* model (also called the *mixed* model) of [12] and [10]. In those models edges can be added as well, and so st-connectivity (directed or not) is again trivial as the single edge (s, t) can always be added and thus every graph is close to having the property. Testing general (all-pairs) connectivity is somewhat harder, and for this constant query testers are generally known, e.g. the one in [7] for the undirected bounded degree case.

Apart from [9], the most related work is that of [8] in which a graph $G = (V, E)$ is given and the properties are properties of boolean functions $f : E(G) \to \{0, 1\}$. In [8] the interpretation of such a function is as an assignment to certain formulae that are associated with the underlying graph G, and in particular can viewed as properties of orientations (although the results in [8] concentrate on properties that are somewhat more "local" than our "global" property of being st-connected). Hence, the results here should be viewed as moving along the lines of the investigation that was started in [9] and [8]. A common feature of the current work with this previous one, which distinguishes these results from results in many other areas of property testing and in particular the dense graph models, is that the algorithms in themselves are rather non-trivial in construction, and not just in their analysis.

The algorithm that we present here for st-connectivity involves a preprocessing stage that is meant to reduce the problem to that of testing a branching program of bounded width. Once this is achieved, a randomized algorithm simulating the test for the constant width branching program from [11] is executed to conclude the result.

In general, the decision problem of st-connectivity of orientations of a given graph is not known to be reducible to constant width branching programs. In fact, it is most probably not the case as st-connectivity is complete for NL (non-deterministic LOG space) while deciding constant width branching programs is in L.

In particular, it is not clear how to deal with high degree vertices or with large cuts. The purpose of the preprocessing stage is to get rid of these difficulties (here it would be crucial that we only want to distinguish between inputs that have the property and inputs that are quite far from the having the property). This is done in several steps that constitute the main part of the paper. In particular we have an interim result in which most but not all edges of the graph are partitioned into constant width layers. This is proved using a concentration lemma for sequences of integers, which is formulated and proved for this purpose.

After the small portion of edges not in constant width layers is dealt with (using a reduction based on graph contraction), we can reduce the connectivity problem to a constant width read once branching program. Once such a branching program is obtained, the result of [11] can be used essentially in a black box manner.

Some interesting related open problems still remain. We still do not know if the property of being *strongly* st-connected is testable with a constant number of queries. The orientation $\vec{G}$ is *strongly* st-connected if there is a directed path in $\vec{G}$ from s to t as well as a directed path from t to s. A more

generalized problem is whether in this model we can test using a constant number of queries the property of being *all-pairs strongly-connected*. Another related property is the property that for a given $s \in V(G)$ every vertex is reachable by a directed path from s. We do not know yet what is the complexity of these problems, although there are some indications that similar methods as those used here may help in this regard.

The rest of this paper is organized as follows. In Section 2 we introduce the needed notations and definitions. Section 3 contains the statement of the main result and an overview of the proof. In Section 4 we reduce the problem of testing st-connectivity in general graphs to the problem of testing st-connectivity in nicely structured bounded-width graphs (we later call them *st-connectivity programs*). Due to space considerations, most of the proofs from Section 4 are moved to the appendix. In Section 5 we reduce from testing st-connectivity programs to testing *clustered* branching programs. The section that deals with converting these clustered branching programs into regular ones, to which we can apply the testing algorithm from [11], appears in the appendix (see Appendix 11). Finally in Section 6 we combine these ingredients to wrap up the proof.

2 Preliminaries

2.1 Notations

In what follows, our graphs are going to possibly include parallel edges, so we use 'named' pairs for edges, i.e. we use $e = e\{u, v\}$ for an undirected edge named e whose end points are u and v. Similarly, we use $e = e(u, v)$ to denote the directed edge named e that is directed from u to v. Let $G = (V, E)$ be an undirected multi-graph (parallel edges are allowed), and denote by n the number of vertices in V. We say that a directed graph $\vec{G}$ is an *orientation* of the graph G, or in short a G-orientation, if we can derive $\vec{G}$ from G by replacing every undirected edge $e = e\{u, v\} \in E$ with either $e(u, v)$ or $e(v, u)$, but not both. We also call G the *underlying graph* of $\vec{G}$.

Given an undirected graph G and a subset $W \subset V$ of G's vertices, we denote by $G(W)$ the induced subgraph of G on W, and we denote by $E(W) = E(G(W))$ the edge set of $G(W)$. The distance between two vertices u, v in G is denoted by $\mathrm{dist}_G(u, v)$ and is set to be the length of the shortest path between u and v. Similarly, for a directed graph $\vec{G}$, $\mathrm{dist}_{\vec{G}}(u, v)$ denotes the length of the shortest *directed* path from u to v. The distance of a vertex from itself is $\mathrm{dist}_{\vec{G}}(v, v) = \mathrm{dist}_G(v, v) = 0$. In the case where there is no directed path from u to v in $\vec{G}$, we set $\mathrm{dist}_{\vec{G}}(u, v) = \infty$. The diameter of an undirected graph G is defined as $\mathrm{diam}(G) = \max_{u,v \in V}\{\mathrm{dist}_G(u, v)\}$. Through this paper we always assume that the underlying graph G is connected, and therefore its diameter is finite.

For a graph $\vec{G}$ and a vertex $v \in V$, let $\Gamma_{in}(v) = \{u : \exists e(u, v) \in E\}$ and $\Gamma_{out}(v) = \{u : \exists e(v, u) \in E\}$ be the set of incoming and outgoing neighbors of v respectively, and let $\Gamma(v) = \Gamma_{in}(v) \cup \Gamma_{out}(v)$ be the set of neighbors in the underlying graph G. Let $\deg_{in}(v)$, $\deg_{out}(v)$ and $\deg(v)$ denote the sizes of $\Gamma_{in}(v)$, $\Gamma_{out}(v)$ and $\Gamma(v)$ respectively. We denote the i-neighborhood (in the underlying undirected graph G) of a vertex v by $N_i(v) = \{u : \mathrm{dist}_G(u, v) \leq i\}$. For example, $N_1(v) = \{v\} \cup \Gamma(v)$, and for all $v \in V$, $V = N_{\mathrm{diam}(G)}(v)$.

2.2 Orientation distance, properties and testers

Given two G-orientations $\vec{G}_1$ and $\vec{G}_2$, the distance between $\vec{G}_1$ and $\vec{G}_2$, denoted by $\Delta(\vec{G}_1, \vec{G}_2)$, is the number of edges in $E(G)$ having different directions in $\vec{G}_1$ and $\vec{G}_2$.

Given a graph G, a property $\mathcal{P}_G$ of G's orientations is a subset of all possible G-orientations. We say that an orientation $\vec{G}$ *satisfies* the property $\mathcal{P}_G$ if $\vec{G} \in \mathcal{P}_G$. The *distance* of $\vec{G}_1$ from the property $\mathcal{P}_G$ is defined

by $\delta(\vec{G}_1, \mathcal{P}_G) = \min_{\vec{G}_2 \in \mathcal{P}_G} \frac{\Delta(\vec{G}_1, \vec{G}_2)}{|E(G)|}$. We say that $\vec{G}$ is ϵ-*far* from $\mathcal{P}_G$ if $\delta(\vec{G}, \mathcal{P}_G) \geq \epsilon$, and otherwise we say that $\vec{G}$ is ϵ-*close* to $\mathcal{P}_G$. We omit the subscript G when it is obvious from the context.

Definition 1. **[(ϵ, q)-tester]** *Let G be a fixed undirected graph and let P be a property of G's orientations. An (ϵ, q)-tester T for the property P is a randomized algorithm, that for any $\vec{G}$ that is given via oracle access to the orientations of its edges operates as follows.*

- *The algorithm T makes at most q orientation queries to $\vec{G}$ (where on a query $e \in E(G)$ it receives as the answer the orientation of e in $\vec{G}$).*
- *If $\vec{G} \in P$, then T accepts it with probability 1 (here we define only* one-sided error *testers, since our testing algorithm will be one).*
- *If $\vec{G}$ is ϵ-far from P, then T rejects it with probability at least $2/3$.*

The query complexity of an (ϵ, q)-tester T is the maximal number of queries q that T makes on any input. We say that a property P is testable if for every $\epsilon > 0$ it has an $(\epsilon, q(\epsilon))$-test, where $q(\epsilon)$ is a function depending only on ϵ (and independent of the graph size n).

2.3 Connectivity Programs and Branching Programs

Our first sequence of reductions converts general st-connectivity instances to well structured bounded-width st-connectivity instances, as formalized in the next definition.

Definition 2 (st-Connectivity Program)**.** *An st-*Connectivity Program *of width w and length m over n vertices (or $CP(w, m, n)$ in short), is a tuple $\langle G, \mathcal{L} \rangle$, where G is an* undirected *graph with n edges and $\mathcal{L}$ is a partition of G's vertices into layers $L_0, \ldots, L_m$. There are two special vertices in G: $s \in L_0$ and $t \in L_m$, and the edges of G are going only between vertices in consecutive layers, or between the vertices of the same layer, i.e. for each $e = e\{u, v\} \in E(G)$ there exists $i \in [m]$ such that $u \in L_{i-1}$ and $v \in L_i$, or $u, v \in L_i$. The partition $\mathcal{L}$ induces a partition $E_1, \ldots, E_m$ of $E(G)$, where E_i is the set of edges that have both vertices in L_i, or one vertex in L_{i-1} and another in L_i. In this partition of the edges the following holds:* $\max_i\{|E_i|\} \leq w$.

Any orientation of G's edges (that maps every edge $e\{u, v\} \in E(G)$ to either $e(u, v)$ or $e(v, u)$) defines a directed graph $\vec{G}$ in the natural way. An st-connectivity program $C = \langle G, \mathcal{L}, \rangle$ defines a property P_C of G's orientations in the following way: $\vec{G} \in P_C$ if and only if in the directed graph $\vec{G}$ there is a directed path from s to t.

Next we define branching programs. These are the objects to which we can apply the testing algorithm of [11].

Definition 3 (Branching Program)**.** *A* Read Once Branching Program *of width w over an input of n bits (or $BP(w, n)$ in short), is a tuple $\langle G, \mathcal{L}, X \rangle$, where G is a* directed *graph with $0/1$-labeled edges, $\mathcal{L}$ is a partition of G's vertices into layers $L_0, \ldots, L_n$ such that* $\max_i\{|L_i|\} \leq w$*, and $X = \{x_0, \ldots, x_{n-1}\}$ is a set of n Boolean variables. In the graph G there is one special vertex s belonging to L_0, and a subset $T \subset L_n$ of* accepting *vertices. The edges of G are going only between vertices in consecutive layers, i.e. for each $e = e(u, v) \in E(G)$ there is $i \in [n]$ such that $u \in L_{i-1}$ and $v \in L_i$. Each vertex in G has at most two outgoing edges, one of which is labeled by '0' and the other is labeled by '1'. In addition, all edges between two consecutive layers are associated with one distinct member of $X = \{x_0, \ldots, x_{n-1}\}$. An assignment*

$\sigma : X \to \{0,1\}$ to X defines a subgraph G_σ of G, which has the same vertex set as G, and for every layer L_{i-1} (whose outgoing edges are associated with the variable x_{j_i}), the subgraph G_σ has only the outgoing edges labeled by $\sigma(x_{j_i})$. A read once branching program $B = \langle G, \mathcal{L}, X\rangle$ defines a property $P_B \subset \{0,1\}^n$ in the following way: $\sigma \in P_B$ if and only if in the subgraph G_σ there is a directed path from the starting vertex s to any of the accepting vertices in T.

Branching programs that comply with the above definition can be tested by the algorithm of [11]. However, as we will see in Section 5, the branching programs resulting by the reduction from our st-connectivity programs have a feature that they require reading more than one bit at a time to move between layers. The next definition describes these special branching programs formally.

Definition 4 (Clustered Branching Program)**.** *A* c-clustered Read Once Branching Program *of width w and length m over an input of n bits (or shortly $BP_c(w,m,n)$) is a tuple $\langle G, \mathcal{L}, X, \mathcal{I}\rangle$, where similarly to the previous definition, G is a directed graph with labeled edges (see below for the set of labels), $\mathcal{L} = (L_0, \ldots, L_m)$ is a partition of G's vertices into m layers such that $\max_i\{|L_i|\} \leq w$, and $X = \{x_0, \ldots, x_{n-1}\}$ is a set of n Boolean variables. Here too, G has one special vertex s belonging to L_0, and a subset $T \subset L_n$ of* accepting *vertices. The additional element $\mathcal{I}$ is a partition $(I_1, \ldots, I_m)$ of X into m components, such that $\max_i\{|I_i|\} \leq c$.*

All edges in between two consecutive layers L_{i-1} and L_i are associated with the component I_i of $\mathcal{I}$. Each vertex in L_{i-1} has $2^{|I_i|}$ outgoing edges, each of them labeled by a distinct $\alpha \in \{0,1\}^{|I_i|}$.

An assignment $\sigma : X \to \{0,1\}$ to X defines a subgraph G_σ of G, which has the same vertex set as G, and for every layer L_i (whose outgoing edges are associated with the component I_i), the subgraph G_σ has only the edges labeled by $\Big(\sigma(x_i)\Big)_{i\in I_i}$. A c-clustered read once branching program $B = \langle G, \mathcal{L}, X, \mathcal{I}\rangle$ defines a property $P_B \subset \{0,1\}^n$ in the following way: $\sigma \in P_B$ if and only if in the subgraph G_σ there is a directed path from the starting vertex s to one of the accepting vertices in T.

Observe that $BP(w,m)$ is equivalent to $BP_1(w,m,m)$.

3 The main result

For an undirected graph G and a pair $s,t \in V(G)$ of distinct vertices, let P_G^{st} be a set of G-orientations under which there is a directed path from s to t. Formally, $P_G^{st} = \{\vec{G} : \mathrm{dist}_{\vec{G}}(s,t) < \infty\}$.

Theorem 3.1. *The property P_G^{st} is testable. In particular, for any undirected graph G, two vertices $s,t \in V(G)$ and every $\epsilon > 0$, there is an (ϵ, q)-tester T for P_G^{st} with query complexity $q = (2/\epsilon)^{2^{(1/\epsilon)\cdot 2^{O(\epsilon^{-2})}}}$*

We can slightly improve the query complexity to $q = (2/\epsilon)^{2^{O((1/\epsilon)^{(1/\epsilon)})}}$ by proving a stronger version of the concentration argument (Lemma 8.2), but we omit this proof from this extended abstract.

3.1 Proof overview

The main idea of the proof is to reduce the problem of testing st-connectivity in the orientation model to the problem of testing a Boolean function that is represented by a *small width read once branching program*. For the latter we have the result of [11] asserting that each such Boolean function is testable.

Theorem 3.2 ([11])**.** *Let $P \subseteq \{0,1\}^n$ be the language accepted by a read-once branching program of width w. Then testing P requires at most $\left(\frac{2^w}{\epsilon}\right)^{O(w)}$ queries.*

By the definition above of $BP(w, n)$, one could already notice that testing the acceptance of a branching program resembles testing st-connectivity, and that the two problems seem quite close. However, there are several significant differences, as noted here.

1. In branching programs, querying a single variable reveals all the edges of its associated layer, while in our case, we need to query each edge of the st-connectivity instance separately.
2. The length of the input in branching programs is the number of layers rather than the total number of edges.
3. The edges in branching program graphs are always directed from L_{i-1} to L_i for some $i \in [n]$. In our case, the graph is not layered, and a pair u, v of vertices might have any number of edges in both directions.
4. In branching programs the graphs have out-degree exactly 2, while an input graph of the st-connectivity problem might have vertices with unbounded out-degree.
5. The most significant difference is that the input graphs of the st-connectivity problem may have unbounded width. This means that the naive reduction to branching programs may result in an unbounded width BPs, which we cannot test with a constant number of queries.

We resolve these points in several steps. First, given an input graph G, we reduce it to a graph $G^{(1)}$ which has the following property: for every induced subgraph W of $G^{(1)}$, the diameter of W is larger than ϵ times the number of edges in W. Then we prove that $G^{(1)}$ can be layered such that most of its edges lie within bounded-width layers. In particular, the total number of edges in the "wide" layers is bounded by $\frac{\epsilon}{2}E(G^{(1)})$. For this we need a concentration type lemma which is stated and proven here for this purpose. Next we reduce $G^{(1)}$ to a graph $G^{(2)}$, which can be layered as above, but without wide layers at all. This in particular means that the number of edges in $G^{(2)}$ is of the order of the number of layers, similarly to bounded width branching programs. In addition, in this layering of $G^{(2)}$ the vertex s is in the first layer, and the vertex t is in the last layer. Then we reduce $G^{(2)}$ (which might be thought of as the *undirected* analogue of a bounded width branching program) to a clustered read once bounded width branching program. Finally we show that these clustered branching programs can be converted into non-clustered branching programs, to which we can apply the test from [11].

4 Reducing general graphs to connectivity programs

In this section we prove our first step towards proving Theorem 3.1. We reduce the problem of testing st-connectivity in a general graph to the problem of testing st-connectivity on an st-Connectivity Program. First we define the notion of reducibility in our context, and then we describe a sequence of reductions that will eventually lead us to the problem of testing read once bounded width BPs. Due to space considerations, almost all proofs from this section were moved into the appendix.

4.1 Reducibility between st-connectivity instances

Let $\mathcal{G}^{st}$ denote the class of undirected graphs having two distinct vertices s and t, and let $G, G' \in \mathcal{G}^{st}$. We say that G is (ϵ, η)-*reducible* to G' if there is a function ρ that maps orientations of G to orientations of G' (from now on we denote by $\vec{G'}$ the orientation $\rho(\vec{G})$) such that the following holds.

- If $\vec{G} \in P^{st}_G$ then $\vec{G'} \in P^{st}_{G'}$
- If $\delta(\vec{G}, P^{st}_G) \geq \epsilon$ then $\delta(\vec{G'}, P^{st}_{G'}) \geq \eta$
- Any orientation query to $\vec{G'}$ can be simulated by a single orientation query to $\vec{G}$.

We say that G is (ϵ)-*reducible* to G' if it is (ϵ, ϵ)-reducible to G'. Notice that whenever G is (ϵ, η)-reducible to G', any (η, q)-tester T' for $P^{st}_{G'}$ can be converted into an (ϵ, q)-tester T for P^{st}_G. Or in other words, (ϵ, q)-testing P^{st}_G is reducible to (η, q)-testing $P^{st}_{G'}$.

In the following section we introduce our first reduction, which is referred to as the reduction from G to $G^{(1)}$ in the proof overview.

4.2 Reduction to graphs having high-diameter subgraphs

An undirected graph G is called ϵ-*long* if for every subset $W \subset V(G)$, $\mathrm{diam}(G(W)) > \epsilon|E(W)|$.

Lemma 4.1. *Any graph $G \in \mathcal{G}^{st}$ is (ϵ)-reducible to a graph $G' \in \mathcal{G}^{st}$ which is ϵ* -long.

We first define a general contraction operator for graphs, and then use it for the proof. Given a graph G let $W \subset V$ be a subset of its vertices, and let $C_1, \ldots, C_t$ be the vertex sets of the connected components of $G(W)$. Namely, for each $C_i \subset W$, the induced subgraph $G(C_i)$ of the underlying graph G is connected, and for any pair $u \in C_i, v \in C_j$ $(i \neq j)$ of vertices, $e\{u, v\} \notin E(G)$. We define a graph G/W as follows. The graph G/W has the vertex set $V/W = (V \setminus W) \cup \{c_1, \ldots, c_t\}$ and its edges are

$$E/W = \Big\{e\{u, v\} : (u, v \in V \setminus W) \wedge (e \in E)\Big\} \cup \Big\{e\{c_i, v\} : (v \in V \setminus W) \wedge \exists_{u \in C_i}(e\{u, v\} \in E)\Big\}$$

Intuitively, in G/W we contract every connected component C_i of $G(W)$ into a single (new) vertex c_i without changing the rest of the graph. Note that such a contraction might create parallel edges, but loops are removed. Whenever $s \in C_i$ for some $i \in [t]$, we rename the vertex c_i by s, and similarly if $t \in C_j$ then we rename c_j by t. In the following a connected component containing both s and t will not be contracted, so we can assume that the distinguished vertices s and t remain in the new graph G/W. Given an orientation $\vec{G}$ of G we define the orientation $\vec{G}/W = \rho(\vec{G})$ of G/W as the orientation induced from $\vec{G}$ in the natural way (note that there are no "new" edges in G/W). The following lemma is proved in Appendix 7.

Lemma 4.2. *Let $W \subset V$ be a subset of G's vertices, such that $\mathrm{diam}(G(W)) \leq \epsilon|E(W)|$. Then G is (ϵ)-reducible to the graph G/W.*

Now the proof of Lemma 4.1 follows by applying this contraction (iteratively) for each "bad" subgraph W, until eventually we get a graph G' in which all vertex subsets W satisfy $\mathrm{diam}(G(W)) > \frac{|E(W)|}{\epsilon}$. If in some stage we have both s and t contained in the contracted subgraph W, then we terminate the whole algorithm by accepting (since in this case all orientations are ϵ-close to being st-connected). Note that this process may result in several different graphs (depending on choices of the set W in each iteration), but we are only interested in one (arbitrary) graph G'. ■

4.3 Properties of ϵ-long graphs

Next we show that an ϵ-long graph G can be "layered" so that the total number of edges in the "wide" layers is bounded by $\frac{\epsilon}{2}E(G)$. We first define graph layering.

Definition 5 (Graph layering and width)**.** *Given a graph G and a vertex $s \in V(G)$, let m denote the maximal (undirected) distance from s to any other vertex in G. We define a* layering $\mathcal{L} = (L_0, L_1, \ldots, L_m)$ *of G's vertices as follows. $L_0 = \{s\}$ and for every $i > 0$, $L_i = N_i(s) \setminus N_{i-1}(s)$. Namely L_i is the set of vertices which are at (undirected) distance exactly i from s. Note that for every edge $e\{u, v\}$ of G either both u and v are in the same layer, or $u \in L_{i-1}$ and $v \in L_i$ for some $i \in [m]$.*

We also denote by $E_i^{\mathcal{L}}$ the subset of G's edges that either have one vertex in L_i and the other in L_{i-1}, or edges that have both vertices in L_i. Alternatively, $E_i^{\mathcal{L}} = E(L_i \cup L_{i-1}) \setminus E(L_{i-1})$. We refer to the sets L_i and $E_i^{\mathcal{L}}$ as vertex-layers *and* edge-layers *respectively. We might omit the superscript $\mathcal{L}$ from the edge-layers notation when it is clear from the context.*

The vertex-width *of a layering $\mathcal{L}$ is $\max_i\{|L_i|\}$, and the* edge-width *of $\mathcal{L}$ is $\max_i\{|E_i|\}$.*

4.3.1 Bounding the number of edges within wide edge-layers

The following lemma (which is proved in Appendix 8) states that in a layering of an ϵ-long graph most of the edges are captured in edge-layers of bounded width.

Lemma 4.3. *Consider the layering $\mathcal{L}$ of an ϵ-long graph G as defined above, and let $I = \{i : |E_i| > 2^{100/\epsilon^2}/\epsilon\}$ be the set of indices of the wide edge-layers. Then the following holds: $\sum_{i \in I} |E_i| \leq \frac{\epsilon}{2}|E|$.*

4.4 Reduction to bounded width graphs

In this section we prove that ϵ-long graphs can be reduced to graphs that have bounded width. In terms of the proof overview, we are going to reduce the graph $G^{(1)}$ to the graph $G^{(2)}$.

Let $G = (V, E) \in \mathcal{G}^{st}$, and let $\mathcal{L} = (L_0, L_1, \ldots, L_m)$ be the layering of G as above. We call an edge-layer E_i *wide* if $|E_i| > \frac{1}{\epsilon} \cdot 2^{100/\epsilon^2}$. Let $\mathcal{W}$ be the set of all wide edge-layers.

Lemma 4.4. *If $G \in \mathcal{G}^{st}$ satisfies $\sum_{E_i \in \mathcal{W}} |E_i| \leq \frac{\epsilon}{2}|E|$ then G is $(\epsilon, \epsilon/2)$-reducible to a graph G' which has no wide edge-layers at all.*

The proof of Lemma 4.4 appears in Appendix 9.

4.5 Reducing bounded width graphs to st-connectivity programs

So far we reduced the original graph G to a graph G' which has a layering $\mathcal{L} = (L_0, L_1, \ldots, L_m)$ of edge-width at most $w = \frac{1}{\epsilon} \cdot 2^{100/\epsilon^2}$, and in which the source vertex s belongs to layer L_0. The remaining difference between G' and an st-connectivity program is that in G' the target vertex t might not be in the last vertex-layer L_m. The following lemma (which is proved in Appendix 10) states that we can overcome this difference by another reduction.

Lemma 4.5. *Let G' be a graph as described above. Then G' is $(\epsilon, \epsilon/2)$-reducible to an st-connectivity program S of width at most $w + 1$.*

5 Reducing st-connectivity programs to branching programs

We now show how to reduce an st-connectivity program to a clustered branching program (recall Definition 2 and Definition 4). First observe that we can assume without loss of generality that if an st-connectivity

program has edge-width w, then its vertex-width is at most $2w$ (since removing vertices of degree 0 essentially does not affect the st-connectivity program, and a vertex in L_i with edges only between it and L_{i+1} can be safely moved to L_{i+1}).

Before moving to the formal description of the reduction, we start with a short intuitive overview. A branching program corresponds to a (space bounded) computation that moves from the start vertex s, which represents no information about the input at all, and proceeds (via the edges that are consistent with the input bits) along a path to one of the final vertices. Every vertex of the branching program represents some additional information gathered by reading more and more pieces of the input. Thus, the best way to understand the reduction is to understand the implicit meaning of each vertex in the constructed branching program.

Given a graph G of a bounded width st-connectivity program, and its layering $L_0, L_1, \ldots L_m$, we construct a graph G' (with layering $L'_0, L'_1, \ldots L'_m$) for the bounded-width branching program. The graph G' has the same number of layers as G. Each level L'_i in G' will represent the conditional connectivity of the vertices in the subgraph $G_i = G(\bigcup_{j=0}^{i} L_i)$ of G. To be specific, the knowledge we want to store in a typical vertex at layer L'_i of G' is the following.

- for every $u \in L_i$ whether it is reachable from s in G_i.
- for every $v, u \in L_i$ whether v is reachable from u in G_i.

Hence, the amount of information we store in each node $x \in L'_i$ has at most $2w + (2w)^2$ many bits, and so there will be at most 4^{2w^2+w} vertices in each L'_i, meaning that the graph G' of the branching program is of bounded width as well.

Lemma 5.1. *Let $\epsilon > 0$ be a positive constant. Given a $CP(w, m, n)$ instance $C = \langle G, \mathcal{L} \rangle$, we can construct a $BP_w(4^{2w^2+w}, m, n)$ instance $B = \langle G', \mathcal{L}', X', \mathcal{I}' \rangle$ and a mapping ρ from G-orientations to assignments on X such that the following holds,*

- *if $\vec{G}$ satisfies P_C then $\sigma = \rho(\vec{G})$ satisfies P_B.*
- *if $\vec{G}$ is ϵ-far from satisfying P_C then $\sigma = \rho(\vec{G})$ is ϵ-far from satisfying P_B.*
- *any assignment query to σ can be simulated using a single orientation query to $\vec{G}$.*

Proof. First we describe the construction, and then show that it satisfies the requirements above.

The vertices of G': We fix i and show, based on the layer L_i of G, how to construct the corresponding layer L'_i of G'. Each vertex in L'_i corresponds to a possible value of a pair (S_i, R_i) of relations. The first relation $S_i \subset L_i$ is a unary relation (predicate) over L_i indicating for each $v \in L_i$ whether there is a directed path from s to v in the subgraph of G induced on $\bigcup_{j=0}^{i} L_j$. The second relation $R_i \subset L_i \times L_i$ is a binary relation over L_i that for every ordered pair (u, v) of vertices in L_i indicates whether there is a directed path from u to v in the subgraph of G induced on $\bigcup_{j=0}^{i} L_j$ (the path can be of length 0, meaning that the R_i's are reflexive). Notice that $|L'_i| = 2^{|L_i|^2+|L_i|} \leq 4^{2w^2+w}$ for all i.

The edges of G': Now we construct the edges of G'. Recall that E'_{i+1} denotes the set of (labeled) edges having one vertex in L'_{i+1} and the other in L'_i. Fix i and a vertex $v \in L'_i$. Let (S, R) be the pair of relations that correspond to v. Let S'' be the set $L_{i+1} \cap \Gamma_{out}(S)$, namely the neighbors of vertices from S that are in L_{i+1}, and set $R'' = \{(v, v) : v \in L_{i+1}\} \cup \{(u, v) : (u, v \in L_{i+1}) \wedge (v \in \Gamma_{out}(u))\} \cup \{(u, v) : (u, v \in L_{i+1}) \wedge \Big((\Gamma_{out}(u) \times \Gamma_{in}(v)) \cap R \neq \emptyset\Big)\}$. Now define R' as the transitive closure of R'', and set

$S' = S'' \cup \{v \in L_{i+1} : \exists_{u \in S''}(u, v) \in R'\}$. Let $v' \in L'_{i+1}$ be the vertex corresponding to the pair (S', R') that we defined above. Then the edges of E'_{i+1} are given by all such pairs of vertices (v, v').

The variables in X': Each variable $x'_i \in X'$ is associated with an edge $e_i \in E(G)$. This association is actually the mapping ρ above, i.e. every orientation $\vec{G}$ of G defines an assignment σ on X'.

The partition $\mathcal{I}'$ of X': Recall that E_i denotes the set of edges of G having either one vertex in L_{i-1} and the other in L_i, or both vertices in L_i. The partition $\mathcal{I}'$ of X' is induced by the partition $\mathcal{L}$ of $V(G)$. Namely, the component I_i of $\mathcal{I}$ contains the set of variables in X' that are associated with edges in E_i. Thus w is also a bound on the sizes of the components in $\mathcal{I}$.

The set $T' \subset L'_m$ of accepting vertices: The set T' is simply the subset of vertices in L'_m whose corresponding relation S contains the target vertex t of G.

Note that each value of a variable in X' corresponds exactly to an orientation of an edge in G. This immediately implies the third assertion in the statement of the lemma. Distances between inputs are clearly preserved, so to prove the other assertions it is enough to show that the branching program accepts exactly those assignments that correspond to orientations accepted by the connectivity program. It is straightforward (and left to the reader) to see that the vertex reached in each L'_i indeed fits the description of the relations R and S, and so an assignment is accepted if and only if it corresponds to a connecting orientation. ■

The branching programs resulting from the above reduction have a feature that they require reading more than one bit at a time to move between layers. Specifically, they conform to Definition 4. The result in [11], however, deals with standard branching programs (see Definition 3), which in relation to the above are a special case in which essentially $m = n$ and all the I_i's have size 1. Going from here to a standard (non-clustered) branching program (in which the edges between two layers depend on just one Boolean variable) is easy. In particular, the following lemma is proved in Appendix 11: *Any $BP_c(w, m, n)$ instance can be converted to a $BP(w2^c, n)$ instance accepting the very same language.*

6 Wrapping up – Proof of Theorem 3.1

We started with a graph G and wanted to construct an (ϵ, q)-test for st-connectivity of orientations of G. In Section 4.1, Section 4.2 and Section 4.3 we constructed a graph G_1 such that if we have an (ϵ, q)-test for st-connectivity in G_1, then we have an (ϵ, q)-test for G. Additionally G_1 has the property that most of the edge-layers in G_1 are of size at most $w = \frac{1}{\epsilon} \cdot 2^{100/\epsilon^2}$. Then in Section 4.4 we constructed a graph G_2 such that if we have an $(\frac{\epsilon}{2}, q)$-test for st-connectivity in G_2 then we have an (ϵ, q)-test for G_1 and hence we have one for G. Moreover G_2 has all its edge-layers of size at most w. Finally in Section 4.5 we built a graph G_3 which has all its edge-layers of width at most $w + 1$, and in addition, the vertices s and t are in the first and the last vertex-layers of G_3 respectively. We also showed that having an $(\frac{\epsilon}{4}, q)$-test for st-connectivity in G_3 implies an $(\frac{\epsilon}{2}, q)$-test for G_2, and hence an (ϵ, q)-test for G. This ends the first part of the proof, which reduces general graphs to st-connectivity programs.

Then in Section 5 from G_3 we constructed a read once $(w + 1)$-clustered Branching Program that has width $4^{2(w+1)^2+w+1}$ so that an $(\frac{\epsilon}{4}, q)$-test for this BP gives an $(\frac{\epsilon}{4}, q)$-test for st-connectivity in G_3. Then we converted the $(w + 1)$-clustered Branching Program to a non-clustered Branching Program which has width $w_1 = 4^{2(w+1)^2+(w+1)}2^{(w+1)}$. Once we have our read once bounded width branching program then by applying the algorithm of [11] for testing branching programs we get an $(\frac{\epsilon}{4}, q)$-test with $q = (\frac{2^{w_1}}{\epsilon/4})^{O(w_1)}$ queries for our problem. Hence by combining all of the above, we get an (ϵ, q) testing algorithm for our original st-connectivity problem, where $q = (2/\epsilon)^{2^{O((1/\epsilon)\cdot 2^{(100/\epsilon^2)})}}$ ■

Appendix

7 Proof of Lemma 4.2

Proof. Fix an orientation $\vec{G}$ of G. It is clear that if $\vec{G} \in P^{st}_G$ then $\vec{G}/W \in P^{st}_{G/W}$. Now assume that $\delta(\vec{G}, P^{st}_G) \geq \epsilon$. Let d and d' denote $\delta(\vec{G}, P^{st}_G) \cdot |E(G)|$ and $\delta(\vec{G}/W, P^{st}_{G/W}) \cdot |E(G/W)|$ respectively. From the definition of the graph G/W it follows that $d' \geq d - \mathrm{diam}(G(W))$. This is true since any st-path in $\vec{G}/W$ can be extended to an st-path in $\vec{G}$ by reorienting at most $\mathrm{diam}(G(W))$ edges in W (by definition, $\mathrm{diam}(G(W))$ is an upper bound on the undirected distance from any "entry" vertex to any "exit" vertex in $G(W)$). From the condition on W we have $|E(\vec{G}/W)| = |E| - |E(W)| \leq |E| - \frac{\mathrm{diam}(G(W))}{\epsilon}$. Combining these two together we have

$$\delta(\vec{G}/W, P^{st}_{G/W}) = \frac{d'}{|E(\vec{G}/W)|} \geq \frac{d - \mathrm{diam}(G(W))}{|E| - \mathrm{diam}(G(W))/\epsilon} \geq \frac{d - \mathrm{diam}(G(W))}{d/\epsilon - \mathrm{diam}(G(W))/\epsilon} = \epsilon$$

In addition, it is clear that we can simulate each query to $\vec{G}/W$ by making at most one query to $\vec{G}$. ■

As a special case we have the following lemma.

Lemma 7.1. *Let $v \in V$ be a vertex of $\vec{G}$, such that $\deg(v) \geq 2/\epsilon$. Then G is (ϵ)-reducible to the graph $G/N_1(v)$.* ■

8 Proof of Lemma 4.3

Before proving Lemma 4.3 we prove an auxiliary concentration lemma. Denote by $\mathcal{A} = \langle a_0, a_1, \ldots, a_m \rangle$ a sequence of integers, where $a_0 = 1$ and for every $i \geq 1$, $a_i = |E_i|$.

Definition 6 (ϵ-good sequence)**.** *Let $0 < \epsilon < 1$ be a positive constant. A sequence $1 = a_0, a_1, \ldots, a_m$ of positive natural numbers is* ϵ-good *if for every $0 \leq k < m$ and $\ell \in [m - k]$ we have that*

$$\sum_{i=k+1}^{k+\ell} a_i \leq \frac{\ell \cdot a_k}{\epsilon}.$$

Claim 8.1. *Let G be a graph in which for any induced subgraph W we have $|E(W)| < \mathrm{diam}(W)/\epsilon$. Then the sequence $\mathcal{A} = \langle a_0, a_1, \ldots, a_m \rangle$ defined above is $\epsilon/4$-good.*

Proof of Claim 8.1. Let us assume the contrary of the claim. Let k and l be such that

$$\sum_{i=k+1}^{k+\ell} a_i > \frac{4\ell \cdot a_k}{\epsilon}$$

Consider the subgraph W defined by the vertices $\cup_{i=k}^{k+\ell} L_i$ and the edges $\cup_{i=k+1}^{k+\ell} E_i$. Now the number of edges in W is clearly $\sum_{i=k+1}^{k+\ell} a_i$. For each vertex v in L_k consider the neighborhood of distance $\ell + 1$ from v, $N_{\ell+1}(v)$, and denote the subgraph it spans by W_v. Notice that each W_v is of diameter at most

$2(\ell+1) \leq 4\ell$, and that the union of the edge sets of the W_v includes the whole edge set of W, so we have $\sum_{v \in L_k} |E(W_v)| \geq \sum_{i=k+1}^{k+\ell} a_i$. The number of vertices in L_k is at most a_k, so by the pigeonhole principle we know that at least one of the vertices v in L_k has at least $\frac{\sum_{i=k+1}^{k+\ell} a_i}{a_k}$ edges in W_v. By our assumption on $\sum_{i=k+1}^{k+\ell} a_i$ we have $|E(W_v)| > \frac{4\ell}{\epsilon} \geq \mathrm{diam}(W_v)/\epsilon$, a contradiction. ∎

Lemma 8.2 (The concentration lemma)**.** *Let $\langle a_0, \ldots, a_m \rangle$ be an ϵ-good sequence and let $B = \{i \mid a_i > 2^{5/\epsilon^2}/\epsilon\}$. Then*

$$\sum_{i \in B} a_i \leq \epsilon \sum_{i=1}^{m} a_i.$$

Proof. Let A be the sum of $a_1, \ldots, a_m$. According to Claim 8.3, that we state and prove further on, we may assume that $a_0, \ldots, a_m$ are monotone non-decreasing as a function of their index without loss of generality. Now we assume that m is a power of 2, and prove that in this case $\sum_{i \in B} a_i \leq \frac{\epsilon}{2} \sum_{i=1}^{m} a_i$. This is sufficient because if m is not a power of 2 then we can add more copies of $a_0 = 1$ in the beginning until m is a power of 2, and doing so will no more than double the sum of the sequence while keeping it ϵ-good.

We first note that since the sequence is ϵ-good then $A \leq m/\epsilon$. In particular it is safe to assume that $m > 2^{4/\epsilon^2}$, because otherwise we would clearly have $B = \emptyset$. Now assume on the contrary that

$$\sum_{i \in B} a_i > \frac{\epsilon}{2} A. \tag{1}$$

Set $p(k) = m(1-2^{-(k+1)})$ and $R(k) = \sum_{i=p(k)+1}^{p(k+1)} a_i$. Obviously (since the sum ranges in the definition of $R(k)$ are disjoint),

$$A \geq \sum_{k=1}^{4/\epsilon^2} R(k). \tag{2}$$

We next show that Assumption (1) implies that for any $k \in [4/\epsilon^2]$ we have that $R(k) > \frac{\epsilon^2 \cdot A}{4}$. This is sufficient since it implies that $\sum_{j=1}^{4/\epsilon^2} R(k) > A$, which contradicts Equation (2).

Let $k_0 = 4/\epsilon^2$. The assumption that the sequence is non-decreasing implies that

$$A \geq a_{p(k_0)} \cdot (m - p(k_0)) = a_{p(k_0)} \cdot m \cdot 2^{-(k_0+1)}.$$

Using that $A \leq m/\epsilon$ we get that $a_{p(k_0)} \leq \frac{2^{(k_0+1)}}{\epsilon} = \frac{2^{4/\epsilon^2+1}}{\epsilon}$.

Consequently, if $a_i > 2^{5/\epsilon^2}/\epsilon$ then $i > p(4/\epsilon^2 + 1)$. Hence for $k \leq k_0$, by Assumption (1) we get that $\sum_{i=p(k)+1}^{m} a_i > \sum_{i \in B} a_i > \frac{\epsilon}{2} A$. On the other hand as $a_0, \ldots, a_m$ is an ϵ-good sequence we know that $\epsilon^{-1} \cdot a_{p(k)} \cdot m \cdot 2^{-(k+1)} \geq \sum_{i=p(k)+1}^{m} a_i$ and therefore by plugging this into the previous inequality we get that $\epsilon^{-1} \cdot a_{p(k)} \cdot m \cdot 2^{-(k+1)} > \frac{\epsilon}{2} A$. Thus, $a_{p(k)} > \frac{\epsilon^2 \cdot 2^k \cdot A}{m}$. Since $a_0, \ldots, a_m$ are monotone non-decreasing as a function of their index we conclude that $R(k) \geq a_{p(k)} \cdot (p(k+1) - p(k)) = a_{p(k)} \cdot m \cdot 2^{-(k+2)}$. Together with the lower bound on $a_{p(k)}$ we get that $R(k) > \frac{\epsilon^2 \cdot A}{4}$. ∎

Claim 8.3. *If $\langle a_0, \ldots, a_m \rangle$ is an ϵ-good sequence, then the sequence $\langle b_0, \ldots, b_m \rangle$ obtained by sorting $a_0, \ldots, a_m$ is also ϵ-good.*

Proof. As the b_i's are monotone increasing as a function of their index, in order to show that they are an ϵ-good sequence we only need to show that for any $k \in [m]$ we have

$$\frac{1}{m-k}\sum_{i=k+1}^{m} b_i \leq \frac{b_k}{\epsilon}$$

(as for monotone sequences the average only decreases if a subsequence is chopped off from the right).

Fix $k \leq m$ and consider the average $\frac{1}{m-k}\sum_{i=k+1}^{m} b_i$. We may assume that each b_i is a renaming of some a_j in the original sequence. Thus the subsequence $B = \langle b_{k+1}, \ldots, b_m \rangle$ corresponds to members in the original subsequence:

$$\langle a_{i_1+1}, \ldots, a_{i_1+j_1} \rangle, \langle a_{i_2+1}, \ldots, a_{i_2+j_2} \rangle, \ldots, \langle a_{i_t+1}, \ldots, a_{i_t+j_t} \rangle$$

where each subsequence $\langle a_{i_r+1}, \ldots a_{i_r+j_r} \rangle$ is a maximal contiguous subsequence in the original sequence whose members were renamed to members of B, and hence their value is at least b_k (as all members in B are such).

On the other hand, the values of $a_{i_1}, a_{i_2}, \ldots, a_{i_t}$ are all bounded by b_k as their renaming does not put them in B. Since $\langle a_1, \ldots, a_m \rangle$ is ϵ-good, this means that for every $1 \leq r \leq t$, the average of the subsequence $\langle a_{i_r+1}, \ldots a_{i_r+j_r} \rangle$ is at most b_k/ϵ. Note that it is safe to assume that b_0 is the renaming of a_0 (which for a good sequence is equal to the minimum 1) and hence $i_1 \geq 0$. Finally, as the average of the subsequence B is clearly a weighted average of the averages of the $\langle a_{i_r+1}, \ldots a_{i_r+j_r} \rangle$ subsequences, it is bounded by b_k/ϵ as well. ■

Now the proof of Lemma 4.3 follows directly from Claim 8.1 and Lemma 8.2. ■

9 Proof of Lemma 4.4

Proof. Recall the definition of G/W (a graph in which a subset of vertices is contracted) from Section 4.2. Let E_i be a wide edge-layer. For every edge $e = e\{u, v\} \in E_i$ define $W_e = \{u, v\}$. We iteratively contract the subgraphs W_e in G, for all edges in all wide edge-layers. Denote the final graph as $G' = (V', E')$.

We claim that after this process G' has no wide edge-layers at all. Formally let $p(i)$ denote the size of the set $\{j | j \leq i \text{ and } E_j \text{ is wide}\}|$. Namely $p(i)$ is number of wide edge-layers in G preceding the vertex-layer L_i. Now we have the following claim:

Observation 9.1. *Let $v \in L_i$ be a vertex in the i'th vertex-layer of G. Then v's representing vertex v' in G' is in the vertex-layer $L'_{i-p(i)}$ of G'.*

Proof. The proof follows by induction on i. ■

The mapping μ sending i to $i' = (i - p(i))$ is monotone non-decreasing, and onto the number of layers in G'. For an index i' of a vertex-layer in G', let $\ell(i')$ denote the largest index in the set $\mu^{-1}(i')$. Recall that E'_i is the set of edges from layer $L'_{i'-1}$ to layer $L'_{i'}$ and within layer $L'_{i'}$ in G'. Note that these edges are exactly the edges that correspond to the edges between layers $L_{\ell(i')}$ and $L_{\ell(i')-1}$ and within $L_{\ell(i')}$ in G. Thus assuming towards a contradiction that E'_i is wide in G', means that $E_{\ell(i)}$ is wide in G . But this is not possible, as $E_{\ell(i)}$ is in the set of edges that were not contracted. As a conclusion, G' cannot have any wide edge-layers.

It is clear that any orientation query to $\vec{G'}$ can be simulated by a single orientation query to $\vec{G}$, and since all we did was contracting edges, if there is a path from s to t in $\vec{G}$ then there is a path from s to t in $\vec{G'}$. Now we only need to show is that the second condition of reducibility holds.

We now show that by changing the direction of at most $\frac{\epsilon}{2}|E'|$ edges we can have a path from s to t in $\vec{G}$ if there was one in $\vec{G'}$. We can always assume that the path in $\vec{G'}$ is simple, i.e. it passes through each vertex at most once. Now each vertex in G' corresponds to a connected subgraph in G. We call a non-trivial subgraph of G *shrunk* if all its vertices, and only them, are represented by a single vertex in G'. Clearly we can extend an st-path in G' to an st-path in G by only reorienting the edges in the shrunk subgraphs of G. We only contracted edges in the wide edge-layers, so the total number of edges in the shrunk components is at most the total number of edges in the wide edge-layers. By the property of G we have that only $\frac{\epsilon}{2}|E|$ of the edges lie in the shrunk subgraphs of G. If by changing the orientation of only $\frac{\epsilon}{2}|E'|$ edges in $\vec{G'}$ we get a path from s to t in $\vec{G'}$, then by changing only $\frac{\epsilon}{2}|E'| + \frac{\epsilon}{2}|E| \leq \epsilon|E|$ edges in $\vec{G}$ we can get a path from s to t in $\vec{G}$, and the second reducibility condition is proved. ■

10 Proof of Lemma 4.5

Proof. Let L_r be the layer to which t belongs in the layering $\mathcal{L}$ of the graph G'. Let $P = \{p_1, p_2, \ldots, p_{m-r}\}$ be a set of $m - r$ new vertices. We define S as follows.

- $V(S) = V(G') \cup P$
- $E(S) = E(G') \cup \left(\bigcup_{i=1}^{m-r-1}\{e_i(p_i, p_{i+1})\}\right) \cup \{e_t(t, p_1)\}$

Any orientation $\vec{G'}$ of G' induces a natural orientation $\vec{S}$ of S; all edges $e \in E(S)$ that are also in $E(G')$ have the same orientation as in $\vec{G'}$, while the orientation of the new edges were defined explicitly above. We also rename t to p_0 and rename p_{m-r} to t in S. Basically we have added a sufficiently long path from the original target vertex to the new target vertex to get S. Now it is easy to verify that G' is indeed $(\epsilon, \epsilon/2)$-reducible to S (assuming that G has at least $1/\epsilon$ edges), and that the width of S is as required. ■

11 Converting clustered branching programs to non-clustered ones

Lemma 11.1. *Any $BP_c(w, m, n)$ instance can be converted to a $BP(w2^c, n)$ instance accepting the very same language.*

Proof. Throughout the proof it is convenient to refer to the vertices of a layer L_i in the clustered branching program as a set of *states*, and to the edges between L_{i-1} and L_i as a *transition function* $f_i : L_{i-1} \times \{0,1\}^{|I_i|} \to L_i$. Namely, $f_i(v, b_1, \ldots, b_{|I_i|})$ is equal to the vertex w in L_i so that (v, w) is an edge labeled with $(b_1, \ldots, b_{|I_i|})$. We shall use an analogue notation for the transition functions in the constructed branching program, $f'_i : L'_{i-1} \times \{0,1\} \to L'_i$. The basic idea of the proof is that instead of reading the entire cluster I_i at once, we read it bit by bit, and use additional states in each layer to store the bits that we have read so far. We need to read at most c bits before we can use the original transition functions, which causes the blowup of up to 2^c in the number of states in each layer. We define the new layers $\{s\} = L'_0, \ldots, L'_n$ of the program inductively. First we define $L_0 = L'_0 = \{s\}$. Now, assuming that we have already converted $L_0, \ldots, L_{i-1}$ into $L'_0, \ldots, L'_j$ such that $L'_j = L_{i-1}$, and calculated the corresponding transition functions $f_k : L'_{k-1} \times \{0,1\} \to L'_k$, we show how to convert L_i into layers $L'_{j+1}, \ldots, L'_{j+|I_i|}$ so that $L'_{j+|I_i|} = L_i$.

For $0 < k < |I_i|$ we set $L'_{j+k} = L_{i-1} \times \{0,1\}^k$, and set $L'_{j+|I_i|} = L_i$. Each layer L'_{j+k} will be associated with the bit corresponding to the k'th member of I_i, which to reduce indexes we shall re-label as y_{j+k}. In the following we denote members of a cross product $A \times B$ as tuples (a, b) with $a \in A$ and $b \in B$. The transition functions $f'_{j+1}, \ldots, f'_{j+|I_i|}$ are set as follows.

- For $k = 1$ we set $f'_{j+1}(v, y_{j+1}) = (v, y_{j+1})$, that is the transition is to the tuple resulting from pairing v with the bit y_{j+1}
- Accordingly, for $1 < k < |I_i|$ we set $f'_{j+k}(v, b_1, \ldots, b_{k-1}) = (v, b_1, \ldots, b_{k-1}, y_{j+k})$, i.e. we concatenate the value of y_{j+k} to the previously collected values.
- Finally, for $k = |I_i|$ we set $f'_{j+|I_i|}(v, b_1, \ldots, b_{|I_i|-1}) = f_i(v, b_1, \ldots, b_{|I_i|-1}, y_{j+|I_i|})$, i.e. we employ the function f_i on all the collected bit values including $y_{j+|I_i|}$.

The accepting subset T' of $L'_n = L_m$ remains the same as the original T. It is now not hard to see that both programs accept the exact same language over $x_1, \ldots, x_n$. ■

The above means that the algorithm of [11] can be employed over the new width $w2^c$ program with the same input.
