PDSP 2026, Lecture 03, 18 August 2026

Generating sequences of numbers

- `range(n)` generates the sequence `0, 1, 2, ..., n-1`
- Use `list(range(n))` to display as a list

In [1]:
```
n = 17
```

In [2]:
```
n
```

Out[2]: 17

In [3]:
```
range(n)  # Like a list, but not quite
```

Out[3]: range(0, 17)

In [4]:
```
list(range(n))  # Make it into a list
```

Out[4]: [0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16]

- `range(n)` translates to `range(0,n)`, implicitly starting with `0`
- Can add an explicit starting point: `range(i,n)` generates `i,i+1,...,n-1`

In [5]:
```
list(range(2,n))
```

Out[5]: [2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16]

- If the starting point is $\geq$ the target, `range` generates an empty sequence

In [6]:
```
list(range(3,3))
```

Out[6]: []

In [7]:
```
list(range(7,4))
```

Out[7]: []

Numbers in Python

- Numbers in Python can be integers (`int`) or reals -- actually rationals -- (`float`)
- Internal representation is different, but arithmetic operation symbols are *overloaded* to apply to both types of numbers
- `+`, `-`, `*` stand for addition, subtraction, multiplication, as usual
- `/` is division, and always produces a `float`

In [8]:
```
8/4
```

Out[8]: 2.0

- There are separate operators for *quotient* (`//`) and *remainder* (`%`)
  - These can also be applied to `float` arguments, but the answer is also `float`

In [9]:
```
8//4
```

Out[9]: 2

In [10]:
```
7//4
```

Out[10]: 1

In [11]:
```
7 % 4
```

Out[11]: 3

In [12]:
```
8.0//3.0, 8.0 % 5.0
```

Out[12]: (2.0, 3.0)

In [13]:
```
9.3//3.05, 9.3 % 3.05
```

Out[13]: (3.0, 0.15000000000000124)

Data types

- A data type is a set of values with associated operations
- Python has two numeric data types, `int` and `float`
- In the FIFA example, we saw text data, which is of type `String` -- we shall examine this later
- The boolean data type has two values `True` and `False`

- Be careful when working with `float`
- Decimal → binary → decimal can create strange "inaccuracies", like `9.3 % 3.05` below

In [14]:
```
9.3//3.05, 9.3 % 3.05
```

Out[14]: (3.0, 0.15000000000000124)

Checking if a number is prime

- Checking if `n` is a prime: assume it is, and flag that is not if we find a factor between `2` and `n-1`

In [15]:
```
n = 17
isprime = True
for i in range(2,n):
```

```
    if n % i == 0:
        isprime = False
```

In [16]:
```
n, isprime
```

Out[16]:
```
(17, True)
```

In [17]:
```
n = 18
isprime = True
for i in range(2,n):
    if n % i == 0:
        isprime = False
```

In [18]:
```
n, isprime
```

Out[18]:
```
(18, False)
```

Optimising the search for factors

- Factors occur in pairs, sufficient to check from 2 to $\sqrt{n}$
- Python has a function `sqrt` to compute square roots
- However it is not automatically available

In [19]:
```
sqrt(n)
```

```
---------------------------------------------------------------------------
NameError                                 Traceback (most recent call last)
Cell In[19], line 1
----> 1 sqrt(n)

NameError: name 'sqrt' is not defined
```

Libraries

- Libraries are collections of code implementing different groups of functions relevant to a given theme
- We will later see libraries specific to data science, machine learning
- The `math` library has mathematical functions like `sqrt`, `log`, `sin`, `cos` etc
- We `import` the `math` library to use it
  - Note that we use `math.sqrt` to tell Python the full context of the function `sqrt`
  - This is useful in case two different libraries have different functions with the same name

In [20]:
```
import math
```

In [21]:
```
n = 17
math.sqrt(n)
```

Out[21]:
```
4.123105625617661
```

Optimised primality checking

- We can optimize our search for factors by restricting the range to `(2,math.sqrt(n))`
- `range` expects only `int` arguments, so use `int()` to convert `math.sqrt(n)` to an `int` -- truncates the fractional part

In [22]:
```
n = 17
isprime = True
for i in range(2,math.sqrt(n)):
    if n % i == 0:
        isprime = False
```

```
---------------------------------------------------------------------------
TypeError                                 Traceback (most recent call last)
Cell In[22], line 3
      1 n = 17
      2 isprime = True
----> 3 for i in range(2,math.sqrt(n)):
      4     if n % i == 0:
      5         isprime = False

TypeError: 'float' object cannot be interpreted as an integer
```

In [23]:
```
n = 17
isprime = True
for i in range(2,int(math.sqrt(n))):  # int(...) truncates a float to an
    if n % i == 0:
        isprime = False
```

In [24]:
```
isprime
```

Out[24]:
```
True
```

In [25]:
```
n = 25
isprime = True
for i in range(2,int(math.sqrt(n))):  # int(...) truncates a float to an
    if n % i == 0:
        isprime = False
```

In [26]:
```
isprime
```

Out[26]:
```
True
```

- We have to be careful, because `range(j,m)` stops at `m-1`
- The code above wrongly claims `25` is a prime -- the search for factors runs from `2` to `4` rather than `2` to `5`

- To fix this, modify the upper bound of `range` to `sqrt(n)+1`

In [27]:
```
n = 25
isprime = True
for i in range(2,int(math.sqrt(n))+1):  # int(...) truncates a float to a
    if n % i == 0:
        isprime = False
```

In [28]:
```
isprime
```

Out[28]:
```
False
```

Large and small numbers

- Python allows us to work with very large (and very small numbers)
- The operator `**` is exponentiation

In [29]:
```
7**3, 2**12
```

Out[29]:
```
(343, 4096)
```

- What is $2^{2^{12}}$, in other words, 2^{4096}?

In [30]:
```
2**(2**12)
```

Out[30]:
```
10443888814131525066917527107166243825799642490473837803842334832839539079715574568488268119349975583408901067144392628379875734381857936072632360878513652779459569765437099983403615901343837183144280700118559462263763188393977127456723346843445866174968079087058037040712840487401186091144679777835980290066869389768817877859469056301902609405995794534328234693030266964430590250159723998677142155416938355598852914863182379144344967340878118726394964751001890413490084170616750936683338505510329720882695507699836163694119330152137968258371880918336567512213184928463681255502259983004123447848625956744921946170238065059132456108257318353800876086221028342701976982023131690176780066751954850799216364193702853751247840149071591354599827905133996115517942711068311340905842728842797915548497829543235345170652232690613949059876930021229633956877828789484406160074129456749198230505716423771548163213806310459029161369267083428564407304478999719017814657634732238502672530598997959960907994692017746248177184498674556592501783290704731194331655508075682218465717463732968849128195203174570024409266169108741483850784119298045229818573389776481031260859030013024134671897266732164915111316029207817380334360902438047083404031541903336

In [31]:
```
2**24
```

Out[31]:
```
16777216
```

In [32]:
```
2**(2**24)
```

```

ValueError   Traceback (most recent call last)

Out[34]:
```
5.562684646268003e-309
```

Computing primes upto `n`

- Instead of checking if `n` is a prime, find all primes upto (and including) `n`
- Generate the sequence `2,3,...,n`
- For each element in this sequence, check if it is a prime
- Accumulate all primes found in a list
  - Recall that `l1 + l2` concatenates two lists into a single list
- Two *nested* loops, use different variables `j` and `i` to iterate

In [35]:
```
n = 50
primelist = []
for j in range(2,n+1):
    isprime = True
    for i in range(2,j): # If we had started with 1, we would have a prob
        if j % i == 0:
            isprime = False
    if isprime:
        primelist = primelist + [j]
```

In [36]:
```
primelist
```

Out[36]:
```
[2, 3, 5, 7, 11, 13, 17, 19, 23, 29, 31, 37, 41, 43, 47]
```

Appending a value to a list

- Can also use `l.append(v)` to add an element `v` to a list
- Note the distinction between `l + [v]` and `l.append(v)`
  - In the first case, we have to make `v` into a singleton list `[v]` to use the operator `+`

In [37]:
```
n = 100
primelist = []
for j in range(2,n+1):
    isprime = True
    for i in range(2,j):
        if j % i == 0:
            isprime = False
    if isprime:
        primelist.append(j)
```

In [38]:
```
primelist
```

Out[38]:
```

```

Functions

- Modularise code into functional units
- Instead of embedding code to check if `j` is a prime, call a function that returns `True` if `j` is a prime and `False` otherwise
- Function definition starts with `def function_name (argument1, argument2, ...):`
- When the function completes, it should report an answer -- return a value through `return(v)`

In [39]:
```
def isprime(n):
    status = True
    for i in range(2,n):
        if n % i == 0:
            status = False
    return(status)
```

In [40]:
```
isprime(17), isprime(25)
```

Out[40]:
```
(True, False)
```

Exiting a function in between

- If we find a factor, we can declare the number to not be a prime without testing more factors
- In the original implementation, we needed to exit the loop
- `return()` automatically exits, so we can use this optimisation in the function

In [41]:
```
def isprime2(n): # An equivalent defn, terminates with False at first fac
    status = True
    for i in range(2,n):
        if n % i == 0:
            status = False
            return(status)
    return(status)
```

In [42]:
```
isprime2(47), isprime2(44)
```

Out[42]: (True, False)

- In fact, we don't even need the variable `status`
- If we find a factor, `return(False)`
- If the search for a factor ends without finding one, `return(True)`

In [43]:
```
def isprime3(n):    # An equivalent defn, without a separate status varia
    for i in range(2,n):
        if n % i == 0:
            return(False)
    return(True)
```

In [44]:
```
isprime3(571), isprime3(573)
```

Out[44]: (True, False)

Using functions

- We can rewrite our code to search for primes upto `n` to call the function `isprime` for each candidate
  - Recall that in our earlier, explicit, code, we had to rename the outer loop variable as `j` to avoid a clash with the loop through potential factors
  - If we use a function, the `i` inside the function is different from the `i` outside the function

In [45]:
```
n = 100
primelist = []
for i in range(2,n+1):
    if isprime(i):
        primelist.append(i)
```

In [46]:
```
primelist
```

Out[46]:
```
[2,
 3,
 5,
 7,
 11,
 13,
 17,
 19,
 23,
 29,
 31,

 53,
 59,
 61,
 67,
 71,
 73,
 79,
 83,
 89,
 97]
```

- We can convert this search for primes upto `n` into another function

In [47]:
```
def primesupto(n):
    primelist = []
    for i in range(2,n+1):
        if isprime(i):
            primelist.append(i)
    return(primelist)
```

In [48]:
```
primesupto(30)
```

Out[48]:
```

Functions and modularity

- Functions modularise code
- Each function has an *interface contract* -- if the input x is valid, the output is $f(x)$
- Can change the implementation of the function so long as the interface contract is upheld
    - Any one of our three implmentations of `isprime` can be used

- For instance, can use a naive implementation as a *prototype* and later replace by a more refined, optimised implementation
